Understanding Calculus and Its Formation

Calculus is formed when dental plaque, a soft and sticky film of bacteria, hardens on the teeth due to mineral deposits from saliva. If plaque is not removed through regular brushing and flossing, it can calcify and turn into calculus, which is much harder and more difficult to remove. The formation of calculus can occur in various areas of the mouth, particularly around the gum line and between the teeth. Understanding the process of calculus formation is crucial for preventing its buildup.

The Role of Plaque

Plaque begins to form on teeth within hours after eating. It is a biofilm that contains bacteria, which can produce acids that erode tooth enamel and irritate the gums. Without proper oral hygiene, plaque can mineralize into calculus within a few days. Regular dental check-ups are vital for monitoring

plaque levels and ensuring timely removal before it turns into calculus.
